Abstract

OPERA has claimed the discovery of superluminal propagation of neutrinos. We analyze the consistency of this claim with previous tests of special relativity. We find that reconciling the OPERA measurement with information from SN1987a and from neutrino oscillations requires stringent conditions. The superluminal limit velocity of neutrinos must be nearly flavor independent, must decrease steeply in the low-energy domain, and its energy dependence must depart from a simple power law. We construct illustrative models that satisfy these conditions, by introducing Lorentz violation in a sector with light sterile neutrinos. We point out that, quite generically, electroweak quantum corrections transfer the information of superluminal neutrino properties into Lorentz violations in the electron and muon sector, in apparent conflict with experimental data.

1 Introduction

The OPERA collaboration has recently announced the measurement of the velocity of neutrinos, as they travel from CERN to the Gran Sasso Laboratory (LNGS) covering a distance of about 730 km [1]. The CERN Neutrino beam to Gran Sasso (CNGS) consists of ν_μ, with small contaminations of $\bar{\nu}_\mu$ (2.1%) and of ν_e or $\bar{\nu}_e$ (together less than 1%). The average neutrino energy is 17 GeV. OPERA has measured the neutrino velocity by taking the ratio between very accurate determinations of distance and time of flight. The distance is defined as the space separation between the focal point of the graphite target (where the proton beam extracted from the CERN SPS collides producing secondary charged mesons that eventually decay into neutrinos) and the origin of the OPERA detector reference frame. High-accuracy GPS measurements and optical triangulations led to a determination of the distance with an uncertainty of 20 cm (monitoring also Earth movements at the level of centimeters). The real advance of OPERA with respect to previous experiments lies in the time tagging system. An upgraded GPS-based timing system at CERN and LNGS allows for time tagging with uncertainties at the level of less than 10 nanoseconds. The neutrino time of flight is then determined by a statistical comparison between the distribution of the neutrino interaction time and the proton probability density function computed from the known time structure of the proton beam. The large data sample[1] of 16111 neutrino events, recorded in a 3-year period, brought the statistical error in the analysis at the same level of the estimated systematic error.

With this procedure, OPERA found the surprising result that neutrinos arrive earlier than expected from luminal speed by a time interval [1]

$$\delta t = (60.7 \pm 6.9_{\rm stat} \pm 7.4_{\rm syst})\,{\rm ns}. \tag{1}$$

This translates into a superluminal propagation velocity for neutrinos by a relative amount

$$\delta c_\nu = (2.48 \pm 0.28_{\rm stat} \pm 0.30_{\rm syst}) \times 10^{-5} \qquad \text{(OPERA)}, \tag{2}$$

where $\delta c_\nu \equiv (v_\nu - c)/c$. The same measurement was previously performed by MINOS (with 735 km baseline and a broad neutrino energy spectrum peaked around 3 GeV). Although not statistically significant, the MINOS result has a central value in the same ballpark of the recent OPERA determination [2]

$$\delta c_\nu = (5.1 \pm 2.9) \times 10^{-5} \qquad \text{(MINOS)}. \tag{3}$$

---

[1] In this paper we use the experimental results based on the original data sample reported in the version 1 of [1]. To remove a possible source of uncertainty, the OPERA collaboration has repeated the analysis with a reduced data sample of 15223 events. The final results presented in the version 2 of [1] are consistent with those quoted below within one standard deviation.

Earlier short-baseline experiments have set upper limits on $|\delta c_\nu|$ at the level of about 4×10^{-5} in the energy range between 30 and 200 GeV [3].

The technical subtleties in the measurement of the neutrino time of flight and the importance of this unexpected result call for further experimental scrutiny. Other experiments, such as MINOS and T2K, are in a position to repeat the OPERA measurement and this can give us decisive information. It is particularly interesting that T2K has a baseline of only 295 km. Finding an early neutrino arrival with a time interval of less than half of what measured by OPERA would rule out a large class of unknown systematics that may affect the present measurement.

Waiting for further developments on the experimental side, theorists can contribute to the debate by analyzing two questions. The first issue is whether the OPERA measurement is already in conflict with other tests of special relativity. The second question is whether we can envisage simple deformations of the Standard Model that can be reconciled with the measurement, possibly suggesting new ways of testing experimentally these scenarios. In this paper, we address such questions.

If the OPERA results are confirmed they will call for a complete reconsideration of the basic principles of particle physics. In a Lorentz-invariant theory, propagation of neutrinos faster than light would imply violation of causality (*i.e.* the CN GS beam becomes GS CN when seen from a sufficiently boosted reference frame). It is extremely hard to envisage a consistent theory having this property. An arguably less radical option is to admit the existence of a preferred reference frame that unambiguously defines causal relations but, by its very existence, breaks Lorentz invariance. In sect. 2 we summarize and analyze the existing constraints on Lorentz violation relevant for our considerations. In sect. 3 we fit the OPERA data and other experimental constraints with energy-dependent neutrino limit velocities. In sect. 4 we present possible models and their problems. Finally our conclusions are contained in sect. 5.

2 Constraints on Lorentz violation

To assess the compatibility of the OPERA result on δc_ν with previous data we should consider three sets of constraints on Lorentz violation[2]: *(i)* bounds from SN1987a; *(ii)* bounds on flavor-dependent δc_ν from neutrino oscillations; *(iii)* bounds on δc_ℓ, the corresponding limit velocity for charged leptons.

---

[2] For a recent review on experimental constraints on Lorentz violation see ref. [4].

2.1 Supernova SN1987a

The detection of neutrinos emitted from SN1987a gave us plenty of information not only on the process of supernova explosion, but also on neutrino properties. The Irvine-Michigan-Brookhaven (IMB) [5], Baksan [6], and Kamiokande II [7] experiments collected $8+5+11$ neutrino events (presumably mainly $\bar{\nu}_e$) with energies between 7.5 and 39 MeV within 12.4 seconds. The time coincidence of these events can be used to constrain the difference in velocity of neutrinos with various energies. Indeed the time delay in the arrival of neutrinos with energy E_1 and E_2, respectively, is equal to

$$\delta t = \frac{d_{\rm SN}}{c} \left[\delta c_\nu(E_2) - \delta c_\nu(E_1)\right], \tag{4}$$

where $d_{\rm SN} = 51$ kpc is the distance of SN1987a. Rescaling a statistical analysis for the case of quadratic energy dependence, $\delta c_\nu \propto E^2$ [8], we obtain the bound

$$|\delta c_\nu(30\,{\rm MeV}) - \delta c_\nu(10\,{\rm MeV})| < 5\times 10^{-13} \text{ at 95\% CL.} \tag{5}$$

However, a larger uncertainty could result from taking into account that the average neutrino energy changes with time during the detection interval of about 10 seconds.

A direct constraint on δc_ν, rather than on the difference between δc_ν at different energies, can be derived from the observation that the optical signal from SN1987a came about 4 hours after the neutrino detection, in good agreement with supernova models. This implies

$$|\delta c_\nu(15\,{\rm MeV})| \lesssim 10^{-9} \tag{6}$$

This limit should be understood with an order-one uncertainty, which takes into account that the precise time delay between light and neutrinos is not known.

In summary, limits on δc_ν from SN1987a are many orders of magnitude more stringent than the positive signal of OPERA. One way to evade the SN1987a bound would be to assume that δc_ν is sizable and positive for neutrinos, but vanishes for antineutrinos. Since the detectors that measured the supernova flux were mainly sensitive to antineutrinos, the SN1987a observation would not contradict the large δc_ν claimed by OPERA. However, we are not aware of a concrete setup that realizes this possibility. A more viable solution exploits the fact that the SN1987a limits are not directly applicable to the OPERA result, since they refer to a different neutrino energy domain, as summarized in fig. 1a.

2.2 Neutrino oscillations

The effective Hamiltonian describing neutrino oscillations can be written as

$$H_{\rm eff} = (1 + \delta c_\nu)\, E + \frac{m^2}{2E}. \tag{7}$$

Here m^2 is the usual 3×3 neutrino mass matrix and δc_ν describes the Lorentz violating effect. In general δc_ν too could be a matrix in flavor space. The observation that neutrino oscillations follow the expected pattern with oscillation phases proportional to L/E, where L is the distance travelled by neutrinos, gives strong bounds on flavor-dependent Lorentz violations.

Off-diagonal elements of the matrix $\delta c_{\nu_i \nu_j}$ are constrained [9, 10] and must satisfy the bound

$$\left|\delta c_{\nu_i \nu_j}\right| < \frac{1}{EL} \approx 2 \times 10^{-19} \left(\frac{\rm GeV}{E}\right) \left(\frac{\rm km}{L}\right). \tag{8}$$

Differences between diagonal elements in the neutrino mass eigenstate basis are similarly constrained, because oscillations involving active neutrinos have been observed and the oscillation dip has been clearly seen in KamLAND ($\bar\nu_e \to \bar\nu_e$ disappearance at $L \sim 100\,{\rm km}$, $E \sim 10\,{\rm MeV}$ due to solar $\nu_e \to \nu_{\mu,\tau}$ oscillations [11]) as well as in K2K, MINOS and T2K [12] energy spectra (ν_μ disappearance due to $\nu_\mu \to \nu_\tau$ atmospheric oscillations at $L \sim 300\,{\rm km}$ and $E \sim 3\,{\rm GeV}$). Too large neutrino velocity differences would split the wave-packets thereby destroying coherence and erasing the observed oscillation dips. Then we obtain the bound

$$\left|\delta c_{\nu_i \nu_i} - \delta c_{\nu_j \nu_j}\right| \lesssim 10^{-(19\div 21)}\ , \tag{9}$$

where the exact value of the exponent depends on the indices i, j.

In summary, flavor-dependent Lorentz violations in the neutrino sector are so strongly constrained that we can hope to explain the OPERA measurement only with a universal limit velocity for all neutrinos. The same conclusion applies to other Lorentz-breaking operators that affect the neutrino velocity. Therefore, it seems reasonable to assume that δc_ν is proportional to the identity matrix in flavor space.

2.3 Charged leptons

Left-handed neutrinos are part of electroweak doublets. Thus gauge interactions can relate Lorentz-violating effects in neutrinos and in charged leptons. This can be a serious concern for any attempt to explain the OPERA measurement in a consistent theoretical framework,

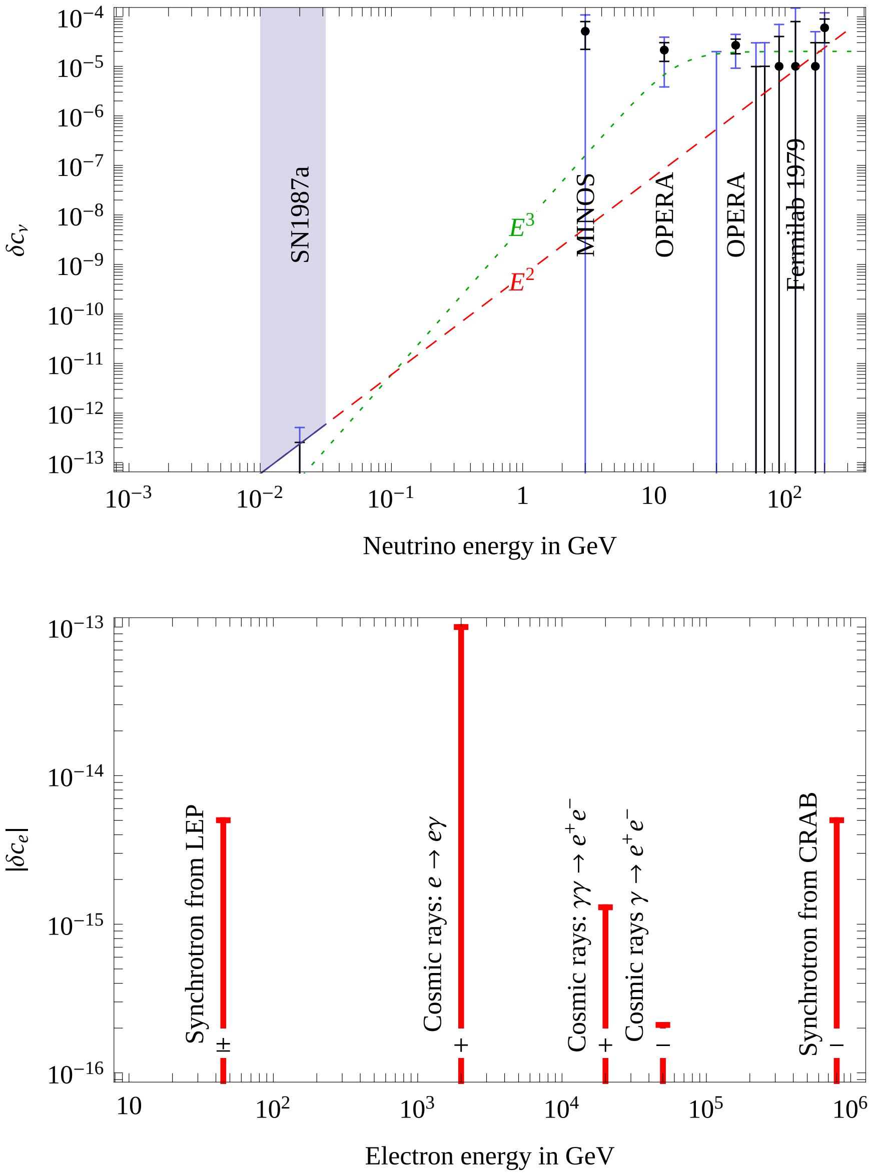

Figure 1: *Top: MINOS, OPERA and* FermiLab1979 *data on* δc_ν*, together with the upper limit from SN1987a (shaded region). Error bars are at* 1σ *(black) and* 2σ *(blue). Overlaid are best fits for* $\delta c_\nu \propto E_\nu^2$ *(dashed red line) and* $\delta c_\nu \propto E_\nu^3/(E_\nu^3 + E_*^3)$ *(dotted green line). Bottom: Upper limits on* $|\delta c_e|$*. The bounds marked with "+" ("−") apply to the case of positive (negative)* δc_e*. See text for an explanation of the different bounds.*

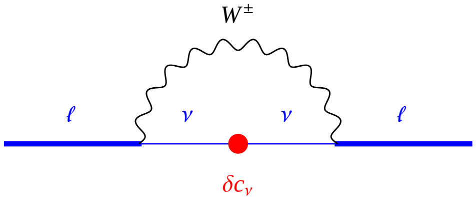

Figure 2: *The Feynman diagram exhibiting how Lorentz violation in neutrinos, represented by the red blob, is transmitted to charged leptons ℓ by quantum electroweak corrections.*

because the present limits on δc_e for electrons are much more stringent than for neutrinos. In fig. 1b we summarize the bounds on δc_e, relating them to the relevant electron energy scales. The labels in fig. 1b correspond to the following observations.

- "Synchrotron from LEP" is the limit $|\delta c_e| < 5 \times 10^{-15}$ derived from agreement between observation and the theoretical expectation of electron synchrotron radiation as measured at LEP [13].
- "Cosmic rays: $e \to e\gamma$" refers to the observation that electron vacuum Čerenkov radiation (the decay process $e \to e\gamma$) becomes kinematically allowed for $E_e > m_e/\sqrt{\delta c_e}$. Since cosmic ray electrons have been detected up to 2 TeV, one deduces $\delta c_e < 10^{-13}$ [14].
- "Cosmic rays: $\gamma\gamma \to e^+e^-$" refers to the process in which high-energy photons are absorbed by CMB photons and annihilate into an electron-positron pair. The process becomes kinematically possible for $E_{\rm CMB} > m_e^2/E_\gamma + \delta c_e E_\gamma/2$. Since it has been observed to occur for photons of about $E_\gamma = 20$ TeV, this implies $\delta c_e < 2m_e^2/E_\gamma^2 \sim 10^{-15}$ [15].
- "Cosmic rays: $\gamma \to e^+e^-$" refers to the process in which a photon decays into e^+e^-, which becomes kinematically allowed at energies $E_\gamma > m_e\sqrt{-2\delta c_e}$. Since photons have been observed up to 50 TeV one deduces $-\delta c_e < 2 \times 10^{-16}$ [14]. The analogous bound for the muon is $-\delta c_\mu < 10^{-11}$ [16].
- "Synchrotron from CRAB" refers to the limit $-\delta c_e < 5 \times 10^{-15}$ deduced from astrophysical observations of inverse Compton scattering and synchrotron radiation [17].

At first sight it may seem that the strong limits on δc_e could be evaded by introducing a Lorentz violating interaction with appropriate Higgs insertions able to select only neutrino fields. One such example is the space rotationally invariant operator $(H^\dagger L^\dagger)\partial_0(LH)$, where

L is the lepton doublet and SU(2) indices are saturated between the fields in parenthesis. Below the weak scale, the Higgs vacuum expectation value leads to an effective operator involving neutrinos but not charged leptons. However, quantum corrections due to weak interactions generate a non-vanishing δc_e proportional to the original δc_ν. This can be seen in the previous example, since the operator $(H^\dagger L^\dagger)\partial_0(LH)$ has an anomalous dimension mixing with the operator $(H^\dagger H)L^\dagger\partial_0 L$, which contributes to δc_e.

The effect is quite general and comes from a one-loop diagram with internal exchange of a W boson and a neutrino with Lorentz-violating insertion (see fig. 2), giving

$$\delta c_e(p) \approx g^2 \int \frac{d^4k}{(2\pi)^4} \frac{\delta c_\nu(k)}{k^2[(k+p)^2 - M_W^2]}. \tag{10}$$

Barring cancellations, the most optimistic situation occurs when δc_ν is as large as the value measured by OPERA in a small energy range around $E_{\rm OPERA} \sim 20\,{\rm GeV}$ and vanishes elsewhere. (In sect. 4 we will construct examples of models that fulfill these conditions). In this way, from eq. (10) we can set a generic lower limit on the value of δc_e based on the OPERA measurement:

$$\delta c_e \gtrsim \left(\frac{E_{\rm OPERA}}{4\pi v}\right)^2 \delta c_\nu(E_{\rm OPERA}) \sim 10^{-9}. \tag{11}$$

This result is clearly in conflict with the limits summarized in fig. 1b.

To justify eqs. (10) and (11) we consider a simple toy model, with a Yukawa interaction between an SU(2) lepton doublet and a sterile neutrino N with Lorentz-violating speed $c(1+\delta c_N)$. This simplified model illustrates well the dynamics of how δc_e is generated, reproducing all the essential features of the more realistic examples later discussed in sect. 4. The Lagrangian of the toy model is

$$\mathscr{L} = \mathscr{L}_{\rm SM} + \bar N i\tilde{\not{\partial}} N + \lambda HLN + \frac{M}{2}N^2 \tag{12}$$

where $\tilde k_\mu \equiv k_\mu - \delta c_N u_\mu (k\cdot u)$ for any quadri-vector k and $u_\mu = (1,0,0,0)$. At tree level one finds $\delta c_\nu(k) = (\lambda v/M)^2 \delta c_N$ up to $k < M/\sqrt{\delta c_N}$, while δc_ν is suppressed by $1/k^2$ at large k.

At high energies, much above the W mass, the Yukawa interaction generates at the one-loop level a correction to the limit velocity of the left-handed electron (and neutrino) in the L doublet:

$$\delta c_L = \frac{\lambda^2 \delta c_N}{6(4\pi)^2}\left[\frac{1}{\epsilon} + \ln\frac{\bar\mu^2}{\Lambda^2} + \mathcal{O}(1)\right] \tag{13}$$

where we used regularization in $d = 4-2\epsilon$ dimensions. In the $\overline{\rm MS}$ renormalization scheme the $1/\epsilon$ pole is reabsorbed in the definition of δc_L and the RGE scale $\bar\mu$ is identified with the low energy scale, $\bar\mu \sim M_W$. Here Λ is the maximal scale at which the theory is valid, which conservatively could be as low as $\Lambda \sim M_W$.

At low energies we can compute the effect by evaluating the contribution of W boson exchange using the unitary gauge, such that the only diagram is the one shown in fig. 2. Neglecting fermion masses ($p^2 = 0$), the correction to the electron self-energy $\Sigma_e(p) = \not{p}$ is

$$\delta\Sigma_e(p) = \frac{g^2(\lambda v)^2}{2} \int \frac{d^4k}{(2\pi)^4} \frac{\gamma_\mu \not{k} \tilde{\not{k}} \not{k} \gamma_\nu P_L}{k^4 \tilde{k}^2} \frac{[-g_{\mu\nu} + (k+p)_\mu (k+p)_\nu / M_W^2]}{(k+p)^2 - M_W^2}. \tag{14}$$

Here we are interested in the Lorentz-violating term inducing a non-vanishing δc_e, which is given by the part of $\delta\Sigma_e$ proportional to $\not{u}$. At leading order in δc_N, the neutrino propagator acquires a Lorentz-violating term proportional to

$$\frac{1}{\not{k}} - \delta c_N \Big[\not{u} \frac{k \cdot u}{k^2} - 2\not{k} \frac{(k \cdot u)^2}{k^4} \Big] \tag{15}$$

and we find a modification of the limit velocity of left-handed electrons,

$$\delta c_e(p) = \frac{g^2}{2(4\pi)^2} \frac{(\lambda v)^2 \delta c_N}{M_W^2} \Big\{ 1 + \frac{1}{6} (\frac{1}{\epsilon} + \ln \frac{\bar{\mu}^2}{M_W^2} - \frac{1}{6}) \Big\} \Big[1 + \delta c_N \mathcal{O}(\frac{p \cdot u}{M_W})^2 \Big]. \tag{16}$$

The first term inside the curly brackets comes from transverse W polarizations and the second (divergent) term comes from the longitudinal W polarization and reproduces the effect in eq. (13). The lowest-order term agrees with eq. (11) after taking into account that one needs M in the same energy range as $E_{\rm OPERA}$, while higher-order terms are model-dependent. Indeed, in this model we obtain

$$\delta c_e(p \ll \frac{M_W}{\sqrt{\delta c_N}}) = \delta c_e(p)|_{\overline{\rm MS}} + \frac{35}{36} \frac{M^2}{(4\pi v)^2} \delta c_\nu. \tag{17}$$

This result holds as long as $M \ll 4\pi v$ (which is the regime relevant for the models considered in sect. 4) because we have used the tree-level relation between δc_N and δc_ν. For $M \gg 4\pi v$, the one-loop correction becomes dominant and eq. (17) should be modified.

In the limit of large electron energy ($p^2 = 0$ with $p \cdot u \gg M_W/\sqrt{\delta c_N}$) the effect can be more easily extracted from the unbroken SU(2) limit. Since the loop function of the integral in eq. (14) depends on the single variable $p \cdot u / M_W$, the high-energy limit is obtained by setting $M_W = 0$, which corresponds to the calculation in eq. (13). In this regime, for dimensional reasons, δc_e remains roughly constant, with a logarithmic dependence on p/M_W, such that the effect cannot be fine-tuned away.

One may believe that the correlation between δc_ν and δc_e is specific to the interaction in eq. (12). To show that this is not the case, let us consider a different way of breaking Lorentz invariance, through a $\Delta L = 2$ term $\frac{1}{2}\kappa[Ni(\partial \cdot u)N + \text{h.c.}]$, which corresponds to an energy-dependent Majorana 'mass-like' term $m_N = \kappa(k \cdot u)$.

The modification of the neutrino velocity is then given by $\delta c_\nu = (\lambda v/M)^2 \kappa^2$, where the square appears because we consider lepton-number conserving neutrino-to-neutrino propagation. For the same reason, the correction to the electron limit velocity is also proportional to κ^2 and consequently again proportional to δc_ν, as in eq. (11). Indeed, the only change in the loop contribution is that eq. (15) becomes

$$\frac{1}{\not{k}} - \kappa^2 \not{k} \frac{(k \cdot u)^2}{k^4} \tag{18}$$

where the Lorentz-breaking term has the same form as the last term in eq. (15). Given that both Lorentz-breaking terms in eq. (15) give non-vanishing contributions to δc_e with comparable order one coefficients and that no other terms are possible, we conclude that the estimate of eq. (11) has general validity.

The muon limit velocity δc_μ is less constrained than in the case of the electron [16, 18]. However the strong bounds on Lorentz violation for non-universal flavor interactions prevents us from restricting superluminal effects to the ν_μ–μ sector.

In summary, the existing limits on δc_e present a formidable obstacle for a consistent interpretation of the OPERA result.

Moreover, the unavoidable non-universality due to the charged lepton masses can propagate at the quantum level an original universal δc_ν into flavor-dependent contributions. Given the strong bounds discussed in sect. 2.2, this could also create serious difficulties in the constructions of viable theories.

3 Model-independent analysis

The OPERA measurement, eq. (2), together with the bounds from SN1987a in eqs. (5)–(6) and those from neutrino oscillations, imply that δc_ν must be nearly flavor-universal and must show a steep energy dependence. It is not difficult to imagine a power law that gives $\delta c_\nu \propto E_\nu^n$, with n positive. The problem however lies in the OPERA data themselves that show no evidence for an energy dependence in the available energy domain. Using only charged-current events inside the detector (a sample of 5489), the collaboration has presented an analysis in which the data are split into two bins of comparable statistics, containing events of energy larger or smaller than 20 GeV. The average energies of the two bins are 13.9 and 42.9 GeV, respectively. The time of neutrino early arrival for the two bins is measured to be [1]

$$\delta t = (53.1 \pm 18.8_{\rm stat})\,{\rm ns} \quad \text{for } \langle E_\nu \rangle = 13.9\,{\rm GeV}$$

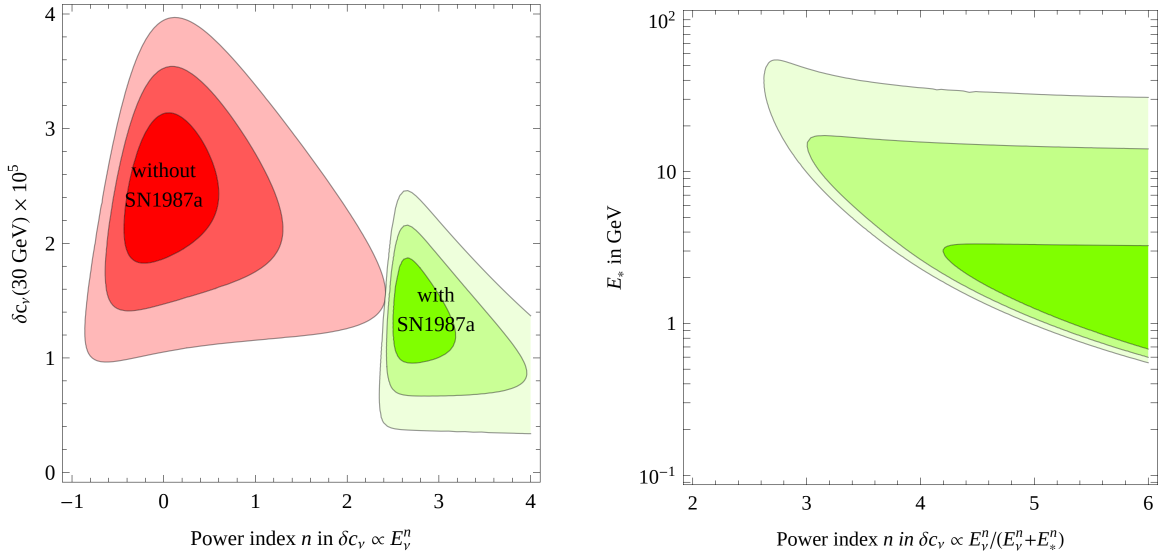

Figure 3: *Left: Fit of the OPERA and MINOS data assuming* $\delta c_\nu \propto E_\nu^n$*. The red contours do not include the SN1987a bound (and have* $\chi^2_{\rm best} = 1$*), while the green ones do (with* $\chi^2_{\rm best} = 14$*). The contours are at* $1, 2$ *and* 3σ *(68%, 95%, 99.73% CL for 2 dof). Right: Same fit assuming* $\delta c_\nu \propto E_\nu^n/(E_\nu^n + E_*^n)$ *and including the SN1987a bound.*

$$\delta t = (67.1 \pm 18.2_{\rm stat})\,\text{ns} \quad \text{for } \langle E_\nu \rangle = 42.9\,\text{GeV}. \tag{19}$$

The difference between the two values is (14.0 ± 26.2) ns, indicating no significant energy dependence.

The situation is illustrated in fig. 1a, where the OPERA and MINOS measurements are plotted together with the SN1987a constraint. While the large value of δc_ν from OPERA requires a power index bigger than 2, such a steep energy dependence is in conflict with the two-bin analysis. This conflict is quantified in fig. 3a, where we fit the data assuming a power law $\delta c_\nu \propto E_\nu^n$. In the global fit we take into account the energy dependence of the OPERA data by appropriately combining the results in eq. (19).

The red region in fig. 3a shows the fit obtained including only OPERA and MINOS data: the best fit has a very good $\chi^2 \approx 1$ and a power-law index $n \approx 0$ is preferred.

The green region shows the global fit, where also the SN1987a data are included. A power-law index $n \leq 2$ is strongly disfavored. The two regions are statistically incompatible, and indeed the global fit[3] including SN1987a has a high $\chi^2 \approx 14$. Furthermore, the global fit is incompatible with the older measurements at higher energies [3], shown in figure fig. 1

---

[3] Of course only the OPERA collaboration can perform a precise fit. However, although details could change, the main features of our analysis are robust.

collectively as "FermiLab1979", because of the growth of δc_ν at high energy.

In order to obtain a good global fit, one must assume a distortion from a simple power law for δc_ν. This situation is less conventional, since it requires the existence of some new physics threshold between the energies of SN1987a (about 10 MeV) and OPERA (about 20 GeV). The same conclusion has also been reached in ref. [19].

In sect. 4 we present examples of models that can produce a distortion of the power law, as suggested by data. Here, we assume a simple change from power-law behavior at low energies to constant behavior at high energies, $\delta c_\nu \propto E_\nu^n/(E_\nu^n + E_*^n)$. As shown in fig. 3b, a statistically acceptable fit is obtained for $n \geq 3$ with $E_* \sim 10$ GeV. MINOS data give a 1-σ preference towards smaller values of E_* and steeper energy growth ($n \geq 4$). An example of such a fit that well interpolates between data and constraints is shown in fig. 1a, where we assume $n = 3$ and $E_* = 15$ GeV.

4 Models

We want to study now how to generate a δc_ν with an energy functional dependence different than a power law. The safest way is to introduce one or more sterile neutrinos N_i with masses M_i within the OPERA energy range and confine the Lorentz-violating interactions in this sector. The relevant Lagrangian is

$$\mathscr{L} = \mathscr{L}_{\rm SM} + \sum_i \left[i\bar{N}_i \bar{\sigma}^\mu \partial_\mu N_i + \left(\frac{M_i}{2} N_i^2 + \lambda_i H L N_i + \text{h.c.} \right) \right] + \mathscr{L}_{\rm Lorentz}. \tag{20}$$

Here $\mathscr{L}_{\rm Lorentz}$ involves only the fields N_i and violates Lorentz invariance. The Yukawa couplings λ_i must be identical for any flavor of the doublet L, but additional contributions to neutrino masses may be present in $\mathscr{L}_{\rm SM}$. As sterile neutrinos have no gauge interactions, Lorentz breaking will be transmitted to active neutrinos in the lepton doublets L at tree level via the active/sterile mixing angles $\theta_i \simeq \lambda_i v/M_i \ll 1$ (experimentally constrained to be $\theta_i < 0.1$) and to charged leptons at loop level.

In the low-energy limit ($E \ll M_i$), the light state mostly coincides with the active one

$$\nu_{\rm light} = \nu + \sum \theta_i N_i + \mathcal{O}(E/M_i). \tag{21}$$

In order to be compatible with the SN1987A bounds, $\mathscr{L}_{\rm Lorentz}$ must have zero projection over the light state at low energies. Assuming, for example, energy-independent Lorentz breaking terms δc_{ij} in the N_i–N_j kinetic mixings, one has

$$\delta c_\nu(E \ll M_i) = \sum_{i,j} \theta_i \theta_j \delta c_{ij} + \mathcal{O}(E^2/M_i^2), \tag{22}$$

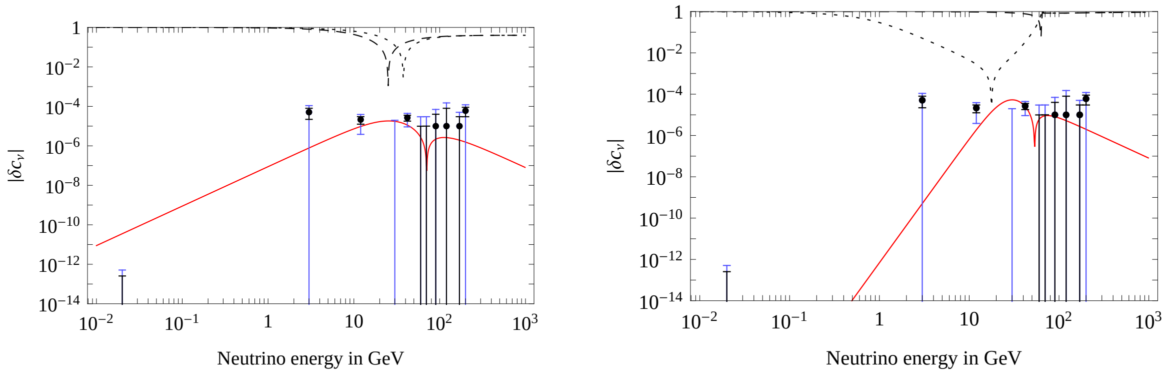

Figure 4: $|\delta c_\nu|$ *of the active neutrino (solid red curve) and of the heavy extra sterile neutrinos that play no active role (dashed and dotted black curves). The left (right) frame refers to the model of section 4.1 (4.2) with the parameter choice described in the text. The dips indicate changes of sign of* δc_ν*, where* δc_ν *for the active neutrino is positive for energies in the OPERA range and below, and negative at higher energies.*

which vanishes for a sector of two sterile neutrinos where the only non-zero terms are θ_2 and δc_{12}. Assuming that only one of the two sterile neutrinos mixes with the active neutrino, and that Lorentz-breaking is only present in the sterile neutrino mixing, we automatically find that at low energy $\delta c_\nu(E) \propto E^n$ with $n \geq 2$. The power suppression at low energy can account for the absence of anomalous effects in SN1987a.

4.1 A model with 2 sterile neutrinos

To protect the SM sector from violation of Lorentz invariance we will adopt the framework of ref. [20] based on supersymmetry. In this context no Lorentz violating operators of dimension less or equal to four are allowed for the superfields describing SM particles. However, a dimension-4 Lorentz breaking kinetic mixing for gauge singlets (such as sterile neutrinos) is allowed. In the superfield language this operator has the form

$$\frac{i}{2}\kappa_{ij}u^\mu \int d^2\theta \; N_i \partial_\mu N_j + \text{h.c.} \tag{23}$$

Here N_i are sterile neutrino chiral superfields with the index i labeling species. The fixed vector u^μ with the components

$$u^\mu = (1, 0, 0, 0) \tag{24}$$

is introduced for convenience to describe Lorentz breaking in a formally covariant way, where space rotational invariance is retained. Finally, the coupling constants κ_{ij} form an antisymmetric matrix, because the symmetric part of the interaction is a total derivative. Thus, this interaction is absent in the case of a single field, and one off-diagonal term is the only possible interaction in the case of two fields. Here we consider the case of two sterile neutrinos.

The operator (23) produces the kinetic mixing for the two sterile neutrinos[4],

$$\mathscr{L}_{\rm Lorentz} = i\kappa\, u^\mu N_1 \partial_\mu N_2 - i\kappa^*\, u^\mu \bar{N}_1 \partial_\mu \bar{N}_2 \; . \tag{25}$$

Thus the full neutrino Lagrangian including mixings with the left-handed neutrino ν is

$$\begin{aligned} \mathscr{L} = {}& i\bar{\nu}\bar{\sigma}^\mu\partial_\mu\nu + i\bar{N}_1\bar{\sigma}^\mu\partial_\mu N_1 + i\bar{N}_2\bar{\sigma}^\mu\partial_\mu N_2 + \left(\frac{M_1}{2}N_1^2 + \frac{M_2}{2}N_2^2 + m_1\nu N_1 + m_2\nu N_2 + \text{h.c.}\right) \\ & + i\kappa\, u^\mu N_1\partial_\mu N_2 - i\kappa^*\, u^\mu \bar{N}_1\partial_\mu\bar{N}_2 \; , \end{aligned} \tag{26}$$

where $m_{1,2} = \lambda_{1,2} v$ and we take $M_1 < M_2$.

In the high-energy regime ($E \gg M_{1,2}$), the sterile and active neutrinos decouple and δc_ν is suppressed. At intermediate energies ($M_1 \ll E \ll M_2$) we can integrate out the heaviest of the two sterile neutrinos, finding

$$\begin{aligned} \mathscr{L} &= i\bar{\nu}\bar{\sigma}^\mu\partial_\mu\nu + (m_1\nu N_1 + \text{h.c.}) + i\bar{N}_1\bar{\sigma}^\mu\partial_\mu N_1 + \left(\frac{M_1}{2}N_1^2 + \text{h.c.}\right) \\ & \quad - \frac{m_2^2}{2M_2}\nu^2 + i\frac{\kappa m_2}{M_2}u^\mu\nu\partial_\mu N_1 + \text{h.c.}\; , \end{aligned} \tag{27}$$

where we have kept only terms with up to one derivative. There is a non-trivial kinetic mixing which, neglecting masses and solving for the equations of motion, gives

$$\delta c_\nu = |\delta|^2 \; , \qquad \delta \equiv \frac{\kappa m_2}{M_2} \; . \tag{28}$$

The quadratic dependence of δc_ν on κ arises because the operator of eq. (25) violates lepton number, while OPERA observes $\nu_\mu \to \nu_\mu$ propagation.

It is interesting to find that the sign of δc_ν is fixed and thus neutrinos are necessarily superluminal. This is a direct consequence of eq. (25), which predicts sterile neutrinos faster than light, while the property of being superluminal is preserved in mixing. The value of δc_ν in eq. (28) is independent of energy, offering the possibility of explaining the flattening of the neutrino speed in the OPERA energy range. In practice, however, the intermediate energy regime ($M_1 \ll E \ll M_2$) should be very small in order to avoid large mixing angles between sterile and active neutrinos.

In the low-energy regime ($E \ll M_1, M_2$) we can integrate out both sterile neutrinos, getting the effective Lagrangian up to one derivative

$$\mathscr{L} = i\bar{\nu}\bar{\sigma}^\mu\partial_\mu\nu + \left(\frac{\kappa m_1 m_2}{M_1 M_2} i u^\mu \nu\partial_\mu\nu - \frac{m_1^2}{2M_1}\nu^2 - \frac{m_2^2}{2M_2}\nu^2 + \text{h.c.}\right) \; , \tag{29}$$

---

[4] We work with two-component spinors and follow the conventions of ref. [21]. The signature of the metric is $(-,+,+,+)$.

We see that apart from the standard neutrino masses we obtain a Lorentz violating kinetic term. However, for a single left-handed neutrino this term is just a total derivative. We should then consider higher-derivative Lorentz-violating interactions. Taking for simplicity $m_1 = 0$, we find

$$\mathscr{L}_{LV} = \frac{\kappa^2 m_2^2}{2M_1 M_2^2}(u^\mu \partial_\mu \nu)^2 + \text{h.c.} \tag{30}$$

This leads to a quartic dispersion relation at low energy:

$$E^2 - p^2 - \frac{|\kappa|^4 |m_2|^4}{M_1^2 M_2^4} E^4 = 0 \, . \tag{31}$$

Thus we obtain

$$\delta c_\nu = \frac{3|\kappa|^4 |m_2|^4 E^2}{2M_1^2 M_2^4}, \tag{32}$$

predicting a power-law suppression proportional to E^2 at low energies.

The expression (31) allows us to estimate the energy E_{trans} where the behavior of δc_ν changes from a quadratic growth to a constant. Equating

$$\frac{|\delta|^4}{M_1^2} E^4 \sim |\delta|^2 E^2 \, , \tag{33}$$

we find

$$E_{\text{trans}} \sim M_1/|\delta| \, . \tag{34}$$

This shows that the transition occurs at energies parametrically larger than M_1.

These analytic estimates are confirmed by a numerical calculation in which we compute exactly the dispersion relation $E_i = E_i(p)$ for the three neutrino states derived from their Dirac equations. The neutrino group velocities is obtained by taking the derivative of E_i with respect to momentum: $c_i = dE_i/dp$. The numerical result corresponding to the choice $M_2 = 2M_1 = 40\,\text{GeV}$, $\theta_2 = 0.1$, $\kappa = 0.7$ is shown in fig. 4a.

This model has a potential problem. The contribution to active neutrino masses in eq. (29) obtained by integrating out N_1 and N_2 is too large. Of course this can be cancelled by other contributions to Majorana masses of active neutrinos. Although this may seem to be a special fine tuning, the cancellation can occur naturally. One example is the case in which the active neutrinos have Yukawa couplings to a single sterile heavy neutrino N_3, while $N_{1,2}$ mix with N_3 in the mass matrix. This generates a rank-one mass matrix for the lighter states. So this problem can be easily bypassed.

Another difficulty is that the model produces at low energy ($E \ll M_{1,2}$) an effect suppressed only by E^2, which is not enough to fit OPERA compatibly with the SN1987A bounds, as illustrated in fig. 4a. This problem can be solved in different ways, as shown by the following examples.

4.2 A model with quadratic mixing term

To remedy to the E^2 low-energy behavior of δc_ν we can add a further derivative in the Lorentz-violating term in eq. (25) and use the Lagrangian

$$\begin{aligned}\mathscr{L} = \;& i\bar{\nu}\bar{\sigma}^\mu\partial_\mu\nu + i\bar{N}_1\bar{\sigma}^\mu\partial_\mu N_1 + i\bar{N}_2\bar{\sigma}^\mu\partial_\mu N_2 + \left(\frac{M_1}{2}N_1^2 + \frac{M_2}{2}N_2^2 + m_2\nu N_2 + \text{h.c.}\right) \\ & + \kappa\, u^\nu u^\mu \partial_\nu N_1 \partial_\mu N_2 + \kappa^*\, u^\nu u^\mu \partial_\nu \bar{N}_1 \partial_\mu \bar{N}_2 \;.\end{aligned} \tag{35}$$

In the high-energy region ($E \gg M_2$) δc_ν is suppressed and dies out. In the intermediate region $M_1 \ll E \ll M_2$ (or more precisely $E_{\text{trans}} \ll E \ll M_2$, where E_{trans} will be computed in eq. (42) below), we obtain the effective Lagrangian

$$\mathscr{L}_{\text{Lorentz}} = \frac{\kappa m_2}{M_2} u^\nu u^\mu\; \nu\, \partial_\nu \partial_\mu N_1 + \text{h.c.}\;, \tag{36}$$

where we have kept terms up to two derivatives. This produces the dispersion relation

$$E^2 - p^2 - \frac{|\kappa|^2 |m_2|^2}{M_2^2} E^4 = 0\;. \tag{37}$$

Hence

$$\delta c_\nu = \frac{3|\kappa|^2|m_2|^2 E^2}{2M_2^2}. \tag{38}$$

We see that in this case the velocity of neutrinos is not constant in the intermediate range but depends quadratically on energy.

At low energies ($E \ll M_1$) we integrate out the remaining sterile neutrino and obtain

$$\mathscr{L}_{\text{Lorentz}} = -\frac{\kappa^2 m_2^2}{2M_1 M_2^2}(u^\mu u^\nu \partial_\mu \partial_\nu \nu)^2\;. \tag{39}$$

This yields the dispersion relation

$$E^2 - p^2 - \frac{|\kappa|^4 |m_2|^4}{M_1^2 M_2^4} E^8 = 0 \tag{40}$$

and hence a δc_ν scaling as the sixth power of energy,

$$\delta c_\nu = \frac{7|\kappa|^4 |m_2|^4 E^6}{2M_1^2 M_2^4}\;. \tag{41}$$

By comparing eqs. (40) and (37) we obtain that the transition between the two regimes occurs at

$$E_{\text{trans}} \sim \sqrt{\left|\frac{M_1 M_2}{\kappa m_2}\right|}\;. \tag{42}$$

These analytic estimates are confirmed by our numerical calculation, as exemplified in fig. 4b, which corresponds to the choice $M_2 = 1\,\text{TeV}$, $M_1 = 1\,\text{GeV}$, $\theta_2 = 0.02$, $\kappa = (30\,\text{GeV})^{-1}$ (in the two-derivative case κ is a dimensionful coupling). In this case we obtain a satisfactory fit of data and constraints, because of the steeper dependence on E at low energies.

4.3 A model with three sterile neutrinos

An alternative approach is to employ three species of sterile neutrinos with Lagrangian

$$\mathscr{L} = i\bar{\nu}\bar{\sigma}^\mu\partial_\mu\nu + \bar{N}_i\bar{\sigma}^\mu\partial_\mu N_i + \left(m_i\nu N_i + \frac{M_i}{2}N_i^2 + \sum_{i<j} i\kappa_{ij}u^\mu N_i\partial_\mu N_j + \text{h.c.}\right) , \qquad (43)$$

where $i, j = 1, 2, 3$. We assume the hierarchy of masses $M_1 \ll M_2 \ll M_3$.

To simplify the calculations let us assume $m_1 = m_2 = \kappa_{12} = 0$. At large energies $E \gg M_3$ the active neutrino decouples from the steriles and propagate with the speed of light. At $M_2 \ll E \ll M_3$ we integrate out the third neutrino and obtain the following Lorentz-breaking contributions

$$\begin{aligned}\mathscr{L}_{\text{Lorentz}} = \; & \frac{\kappa_{13}m_3}{M_3}iu^\mu\nu\partial_\mu N_1 + \frac{\kappa_{23}m_3}{M_3}iu^\mu\nu\partial_\mu N_2 \\ & + \frac{\kappa_{13}^2}{2M_3}(u^\mu\partial_\mu N_1)^2 + \frac{\kappa_{23}^2}{2M_3}(u^\mu\partial_\mu N_2)^2 + \frac{\kappa_{13}\kappa_{23}}{M_3}u^\mu u^\nu\partial_\mu N_1\partial_\nu N_2 \; .\end{aligned} \qquad (44)$$

The velocity of the active neutrino in this regime is given by

$$\delta c_\nu = |\delta_{13}|^2 + |\delta_{23}|^2 \; , \qquad \delta_{13} \equiv \frac{\kappa_{13}m_3}{M_3} \; , \quad \delta_{23} \equiv \frac{\kappa_{23}m_3}{M_3} \; . \qquad (45)$$

At lower energies ($M_1 \ll E \ll M_2$) we integrate out the second neutrino and the Lorentz breaking part becomes

$$\mathscr{L}_{\text{Lorentz}} = \frac{\kappa_{13}m_3}{M_3}iu^\mu\nu\partial_\mu N_1 + \frac{\kappa_{13}^2}{2M_3}(u^\mu\partial_\mu N_1)^2 + \frac{\kappa_{23}^2 m_3^2}{2M_2M_3^2}(u^\mu\partial_\mu\nu)^2 \; , \qquad (46)$$

where we have considered only terms up to two derivatives. The third term here gives the quadratic growth of δc_ν with energy.

Finally, at $E \ll M_1$ we integrate out N_1 and obtain

$$\mathscr{L}_{LV} = \frac{m_3^2}{2M_3^2}\left[\frac{\kappa_{13}^2}{M_1} + \frac{\kappa_{23}^2}{M_2}\right](u^\mu\partial_\mu\nu)^2 \; . \qquad (47)$$

The quadratic growth can be shut off at the price of the fine-tuning condition $(\kappa_{13}/\kappa_{23})^2 \simeq -M_1/M_2$. The next operator is quartic in derivatives and will give an E^6 dependence of δc_ν on energy.

Let us conclude our discussion on these models with an important consideration. The models described here realize the optimal situation in which δc_ν is large only at OPERA energies: at lower energies there is a power-law suppression and at higher energies δc_ν decreases because energy dominates over the active/sterile mass mixing term. In spite of that, the quantum corrections to the velocity of charged leptons ℓ is too large. For instance, in the model of sect. 4.1, we find

$$\delta c_\ell \approx \frac{\lambda_2^2}{(4\pi)^2}\kappa^2 \tag{48}$$

in agreement with the generic estimate of eq. (11). Note that supersymmetry cannot be invoked as a solution, because at momenta of the order of the OPERA energies the wino loop contribution cannot cancel the $W^\pm$ loop.

5 Conclusions

It has been often speculated that Lorentz invariance can be violated in new frameworks beyond the Standard Model, especially in the context of various quantum gravity scenarios, such as space-time foam [22], string theory [23], Hořava gravity [24], extra dimensions with asymmetric space-time warping factors [25], or inhomogeneous Higgs backgrounds [26]. Tests of Lorentz invariance can provide us with precious hints of physics at energy scales much beyond those directly probed in colliders and the experimental discovery of an actual Lorentz violation in nature would have a revolutionary impact on our understanding of the fundamental principles of the particle world.

The recent OPERA measurement, pointing towards evidence for superluminal propagation of neutrinos, opens an exciting perspective. Careful scrutiny of the OPERA methodology and confirmation from other experiments is certainly required before the measurement can be accepted. From the theoretical point of view, the result is quite surprising, not because of the violation of a sacred principle of special relativity, but because of the size of the effect. The amount of Lorentz violation in the neutrino sector required to explain the effect is much larger than the typical bounds that have been extracted for other Lorentz-violating parameters. This poses a question of logical consistency of the new experimental result.

In this paper, we have shown that the OPERA measurement is not necessarily inconsistent with other tests of special relativity in the neutrino sector, but requires very particular assumptions on δc_ν, the relative difference between the neutrino and photon limit velocities. Various observational constraints, reviewed in sect. 2, force δc_ν to be nearly flavor universal, to drop steeply at low energies ($E_\nu < 10$ GeV) and remain roughly constant in the OPERA energy range (around 10 to 40 GeV). Such a peculiar behavior is unexpected but, as shown in sect. 4 with the help of several illustrative models, can be accounted for by introducing sterile neutrinos with Lorentz-violating interactions and masses in the OPERA energy range.

As discussed in sect. 2, a fairly generic and formidable constraint on any interpretation of the OPERA measurement comes from δc_e, the relative difference between electron and photon limit velocities. Even if we restrict the original Lorentz violation to the neutrino sector, quantum corrections due to weak interactions will generally pollute the electron sector as well. Barring unknown cancellations, the resulting effect is too large, showing conflict between present bounds on δc_e and the OPERA measurement. Fine-tuning the value of δc_e at a particular energy cannot cure the problem, because there are strong bounds on δc_e applicable at several different energies.

Much work has still to be done, both on the experimental and the theoretical front, before the fate of the OPERA measurement and its impact on physics will be determined.

Note added

After this paper was published, the authors of ref. [27] presented another strong constraint on superluminal interpretations of the OPERA result, based on energy loss from neutrino decay. Their constraint is as numerically stringent as the constraint presented here, based on loop contributions to δc_e, but more direct. Ref. [27] assumed an energy-independent δc, but their argument is fairly robust, since any dispersion relation leading to a superluminal neutrino, like the ones we consider, implies that a neutrino decay process is kinematically allowed. Indeed, let us consider the decay process $\nu(p) \to \nu(p')X$, where $X = e^+e^-$ or any light final state. The process is allowed when the invariant mass of X is positive or, in other words, when the difference of the 4-momenta of the two neutrinos is time-like,

$$E(p) - E(p') > p - p'. \tag{49}$$

Here $E(p)$ is the neutrino energy for a generic dispersion relation and p (p') is the momentum of the initial-state (final-state) neutrino. For a superluminal neutrino we approximately find

$$c > 1 \quad \Rightarrow \quad c = \frac{dE}{dp} \approx \frac{E(p) - E(p')}{p - p'} > 1. \tag{50}$$

Thus a superluminal neutrino always has kinematically-allowed decay channels, independently of its dispersion relation.
